Abstract

Introduction:
The high prevalence of apical periodontitis (AP) of endodontic origin raises an important public health problem. Root canal treatment (RCT) and crown restoration (CR) have an effect on its prevalence. This cross-sectional study was performed to assess the effect of RCT and CR on the prevalence of AP.

Materials and methods:
Two observers assessed 608 teeth with RCT belonging to patients who were referred to the radiology ward of the dental school at the Shahid Sadoughi University of Medical Sciences, Yazd, Iran, in 2011–2012 in the form of 152 panoramic radiographs. The quality of RCT, including length/density of root restoration, and crown restoration and the prevalence of AP were recorded from patients’ medical files. Data were analyzed by chi-square test, one-way ANOVA, and logistic regression model using SPSS (ver. 19).

Results:
The frequency of AP in teeth with RCT was 50.5%. Appropriate CR and RCT was observed in 348 (57.2%) and 168 (30.6%) of teeth, respectively. Furthermore, 36.8% of teeth with appropriate and 68.8% with inappropriate crown restoration showed AP, and the difference was significant (p < 0.001). Prevalence of AP was significantly lower in teeth with acceptable RCT than in those with unacceptable RCT (p < 0.001). Teeth with unacceptable RCT/CR showed AP 6 times more frequently than teeth with acceptable RCT/CR.

Conclusion:
The findings showed that a considerable number of teeth in Yazd had RCT/CR with unacceptable results and that the quality of both RCT and CR may affect the prevalence of AP. Therefore, considerable efforts are required to improve endodontic and restorative treatment standards.

Key words:
• Root Canal Therapy • Tooth Crown • Apical Periodontitis • Radiology
Introduction

Apical periodontitis (AP) is a multi-factorial disease mostly caused by bacteria.\(^1\) The disease results from the reaction of periapical tissue to mild irritations, such as pulp necrosis or inappropriate root canal treatment (RCT).\(^2\) RCT is done to prevent AP and to create an appropriate condition for apex healing \(^3-5\), although some RCTs may not be successful because of technical errors or difficulty in applying cleaning devices to the root canal.\(^6, 7\) The prevalence of AP in teeth with RCT is about 24.5%–65.8% \(^5, 7, 9\); however, its prevalence in teeth without RCT is about 4–9%.\(^9-12\)

Panoramic radiography has been used in some studies because of its high validity and low patient exposure.\(^13-17\) Various indices are used for radiographic assessment of the quality of root canal and crown restorations and the condition of teeth apices.\(^18-20\) The periapical index (PAI) is one of the indices used as a reference for the assessment of AP.\(^20\) Some studies have assessed the role of coronal sealing on apex healing.\(^9, 11, 16\) Penetration of saliva from the crown to the interior of the tooth that has received RCT creates a damp environment that is suitable for the growth of bacteria.\(^8, 21, 22\)

Considering the importance of crown and root canal treatment and its association with AP, this study was designed to assess the prevalence of AP and its association with the quality of root and crown restorations in patients referred to the oromaxillofacial radiology ward of dental schools.

Materials and Methods

A total of 608 teeth with RCT in 152 digital panoramic radiographs, obtained in 2011–2012, were randomly selected. The subjects, who were referred to the dental school for the first time, were included in the study and those younger than 18 years old, possessing lesser than 10 teeth, and having had an RCT in the last year were excluded from the study. Additional exclusion criteria were systemic disease, pulp stone, teeth with post and core, and extreme premolar overlap in the radiography. Anterior teeth were not included in our study because of vertebra column superimposition in panoramic view on the anterior site. Differentiation between scar and apical periodontitis was obtained from the patients’ history. The study was approved by the ethics committee of the Shahid Sadoughi University of Medical Sciences (ethical code 138846).

Radiographs were obtained by a digital device (Proline XC, Planmeca, Helsinki, Finland) under the following exposure parameters: exposure: 66–70 KVP, intensity: 8–10 mA, and duration: 10–12 s). Images were observed on a computer by Romexis 2.9.2 Planmeca software. The monitor size was 17 inches with 1024-pixel resolution. The contrast and brightness of the monitor was set by the observers, who were an oromaxillofacial radiologist and an endodontist. For consistency, 30 panoramic radiographs were reviewed and reported upon by both observers separately. Then, all radiographs were interpreted by the shared opinion of both observers. Teeth in which the root or pulp chamber were radiopaque were considered as being RCT. Length and density of root treatment, the overall quality of root treatment according to length/density, the quality of crown restoration, presence of AP, and its score (Table 1) were also assessed. The periapical situation of teeth was scored with the PAI index and the teeth were divided into 5 groups\(^25\). A score of 3 or higher was considered to be AP. Because this study was conducted according to the radiographic findings, leakage was not assessed. Data were analyzed with SPSS using the chi-square test, Fisher’s exact test, and logistic regression model. Level of significance was set at p < 0.05.

Results

This study was conducted on 3936 teeth from 152 subjects. 608 teeth (15.41%) had RCT. Table 2 shows the frequency distribution of subjects in different age groups. RCT teeth with AP were less frequent in males (30.2% vs. 69.7%). The oral hygiene of the selected population and the number of remaining and lost teeth are shown. Table 3 shows the frequency of RCT teeth and RCT teeth with AP. Table 4 shows the condition of the tooth restorations in terms of length and density. We found a significant association between the frequency of AP and length/density of canal in RCT teeth (p < 0.001) (Table 5).

Table 6 shows the multiple logistic regression analysis for the effect of two independent var-
The parameters for the combined quality of CR and RCT are also shown in Table 5. Both of these variables were adequate in only 19.9% of the teeth studied, and approximately one-sixth of these teeth (19%) had AP. When tested against other combinations of the quality parameters, RCT/CR was significantly less than acceptable (p < 0.001). Table 7 shows the multiple logistic regression analysis for the effect of two independent variables (RCT and CR quality) on periapical condition. The odds of AP/normal periodontal status in cases with both unacceptable RCT and CR was more than 6 times greater compared with cases with acceptable RCT/CR.

Discussion

The main objective of RCT is prevention or treatment of AP lesions. According to studies in controlled situations, the success rate of RCT is more than 90%, but some cross-sectional studies on human populations have shown a success rate of 35%–60% for this treatment. (23, 25) RCT and post-treatment factors (e.g., length and density of root restoration and quality of crown restoration) are the main factors in the success rate of RCT (presence or lack of AP). (26)

In this study, panoramic radiography was used to assess the condition of AP and the quality of root canal or crown treatments. Length and density of restoration were used as the indices of acceptable root treatment, although panoramic radiography underestimates the real frequency of AP; however, because of a high correlation between intra-oral and panoramic radiographies and overestimation of panoramic radiography in comparison to intra-oral radiography (27-29), it seems that recording the prevalence of periodontitis using panoramic radiography is a satisfactory method. (26) Because of the study limitations, canal length was classified as acceptable and unacceptable.

The direct association between the quality of RCT and the prevalence of AP has been seen in previous studies as well. (2, 26) Asgary et al. found AP in 29.1% of RCT teeth, consistent with the results of the current study (26); however, in Kakehashi’s study, the prevalence of AP in teeth with acceptable RCT was 16.5%, which is probably because of the higher quality of treatment in this study. (2)

When we assessed the quality of root restorations according to the length and density separately, it was determined that the length and density of restorations were appropriate in 59.4% and 40.6% of cases, respectively. Thus, it was shown that both factors play an important role in the quality of RCT and the prevalence of AP. Asgary et al. (26), Deamkashan et al. (23), and Kirkevang et al. (8) found similar results.

In the current study, teeth that received RCT in the last year were included; since the majority of healing takes place in the first six months after treatment, size of AP is affected by the treatment procedure. In this study, prevalence of AP in all teeth was 50.5%, but this measure in different studies ranged from 20% to 65%. (28-31) This difference is probably because of the patient’s level of oral health and the skill of the dentists.

In the current study, 69.7% of AP cases were given a score of 3, which agrees with the findings of Asgary et al. (26) With increasing score, the size of lesion and its effect on the surrounding tissue will increase. The size of lesion may also affect the decision for treatment (32), but the size does not affect the patient’s improvement. Large lesions only need a longer time to be cured. (33) The
Influence of the Quality of Root Canal Treatment and Crown Restoration

Conclusion

The findings of this study confirmed the results of past studies about the effect of the quality of RCT and CR on the occurrence of AP. Therefore, in order to cure teeth with pulp disease, all stages of treatment should be performed with caution. It is recommended that additional studies be conducted to clinically assess crown sealing conditions using both intra-oral and panoramic radiography.

Abstract

Introduction:
Head and neck sarcomas involve a group of rare malignant diseases with a high histological variability involving various anatomical sites that can lead to under-reporting of the true incidence of these neoplasms. This study aimed to epidemiologically investigate the occurrence of sarcomas of the head and neck within the past 20 years in Yazd, Iran (1994–2014).

Materials and methods:
In this descriptive, cross-sectional and retrospective study, 16114 patient’s records with malignant tumors were examined via the census method, which were available in the archives of 8 main treatment centers in Yazd, Iran within a 20-year period. Age, sex, occupation, habitat, type of sarcoma, tumor location and grade, metastasis, recurrence, and history of head and neck irradiation were recorded. Data were analyzed in SPSS software version 17.

Results:
Among 586 cases of sarcomas, 59 cases (10.06%) were identified with head and neck sarcomas. The mean age of the patients was 32.22 ± 8.31 years, of which 26 (44.01%) patients were males and 33 (55.9%) were females. Soft tissue sarcomas were noted in 41 cases (69.5%); rhabdomyosarcoma was the most common (27.1%). Eighteen (30.5%) patients had hard tissue sarcomas; osteosarcoma (15.3%) was the most common. Soft tissues of the head and neck were the most (49.20%) involved sites. Most sarcomas were low grade. In 5 patients (8.5%), metastases occurred to the head and neck, and the tumor relapsed in 16 patients (27.1%).

Conclusion:
The findings of the current study were in agreement with those of other reports referred to in different studies. This suggests that the epidemiology of head and neck sarcomas in Yazd, Iran is similar to other geographical regions.

Prevalence of Head and Neck Sarcomas in the Main Health Centers

**Introduction**

Sarcomas involve a rare and heterogeneous variety of malignant tumors of mesenchymal origin with a specific and distinct histopathology. The mesenchymal cells can develop into tumors affecting the soft tissues of muscle, fat, and fibrous tissue. Bone and nerves can also be involved. Occasionally, these tumors are associated with trauma, genetic syndromes as well as exposure to previous radiation, though there is mostly no apparent cause. Pathological classification is most valuable in the treatment and prognosis of head and neck sarcomas.

The incidence of sarcoma is more prevalent in children than adults. Approximately 1% of all adult cancers and 10%–20% of pediatric cancers are sarcomas. About 5%–15% of adult sarcomas are in the head and neck region; 35% of children are diagnosed with head and neck sarcomas. The findings of different studies have revealed that the incidence of sarcoma is more in men than in women, which is about 50% to 60%.

Common soft tissue sarcomas in order of frequency include liposarcoma, malignant fibrous histiocytoma, fibrosarcoma, rhabdomyosarcoma, leiomyosarcoma, synovial sarcoma, malignant peripheral nerve sheath tumors, angio-sarcoma and kaposi sarcoma, whereas hard tissue sarcomas in order of frequency entail osteosarcoma, chondrosarcoma, as well as Ewing’s sarcoma. The results of some studies conducted in Iran demonstrated that 60% of sarcomas occurred in males with a mean age of 36 years, that the most common sarcomas in adults were malignant fibrous histiocytoma and synovial sarcoma and kaposi sarcoma, whereas hard tissue sarcomas in order of frequency entail osteosarcoma, chondrosarcoma, and Ewing sarcoma, and rhabdomyosarcoma in the were the most common sarcomas.

The ratio of bone sarcoma to sarcoma of soft tissue was 3:1 in patients aged under 16 years and 1:3 among adults. In a study conducted on the epidemiology of soft tissue sarcomas in Shahid Sadoughi hospital of Yazd in 2005, the most common sarcomas were synovial sarcoma and malignant fibrous histiocytoma respectively among males and females. The study findings indicated that the sarcoma incidence in Yazd was similar to that of Western countries.

Epidemiological studies provide vital information that forms the basis of future research. Because investigating the prevalence of sarcomas in the head and neck has received scant attention in Iran, the present study is intended to provide the epidemiology of sarcomas of the head and neck over the past 20 years in Yazd, Iran (1994–2014) based on the histopathologic examinations.

**Materials and Methods**

In this descriptive, cross-sectional, and retrospective study, 16,114 patients records, diagnosed as malignant tumors were examined from the archive of the Shahid Sadooghi Dental School and several other hospitals (Shahid Sadoughi, Shahid Rahnemoon, Mojibiyan, Mortaz, Shohadaye Kargar, Seyedosghada and Savaneh Sookhtegi) over a 20-year period (1994–2014). The records were obtained by proposing a research study from the Shahid Sadoughi medical university of Yazd (Ethical code: p.17.1.77710; date: 1393.4.22).

It should be noted that case records that were incomplete or cases in which the patients reported a written dissatisfaction were excluded from the study. In order to glean the study data, a checklist was devised consisting of the following variables: case record number, pathology department identification number, age, sex, occupation, place of residence, type of sarcoma, tumor location, tumor grade, the occurrence of metastasis, recurrence, history of head and neck irradiation. The patients’ medical records as well as their pathology reports available in the mentioned health centers were collected and analyzed utilizing the SPSS software (Ver. 17) through descriptive statistics.

**Results**

Out of 16,114 cases examined in this study, 586 cases (3.65%) of patients were diagnosed with sarcomas, among which 59 patients (10.06%) suffered from sarcomas of the head and neck, the study cohort. The mean age of the patients was 32.22 ± 8.31 years with an age range of 1.5–83 years, of which 17 patients (28.8%) were <16 years of age, whereas 42 patients (71.2%) were > 16 years. A total of 26 patients (44.05%) were males and 33 (55.9%) were females. More than half of patients (59.3%) lived in Yazd (Table 1). As demonstrated in Table 2, 41 cases (69.5%) of...
sarcomas belonged to soft tissue sarcomas. The most prevalent type of soft tissue sarcomas was rhabdomyosarcoma (27.1%).

Among the bone tissue sarcomas, affecting 18 patients (30.5%), osteosarcoma (15.3%) and chondrosarcoma (11.9%) were the most prevalent (Table 2).

Rhabdomyosarcoma was reported to be the most common sarcoma (13.5%) in the both the age groups, as well as in men (10.2%) and women (16.9%). The lowest incidence was found to be Kaposi sarcoma, which was only observed in one man >16 years old (1.7%) (Table 2).

The most areas commonly affected were soft tissues of the head and neck (49.2%), jaw bones (35.6%) as well as the head and skull bones (15.3%). With respect to tumor grading, most of the sarcomas were of the low grade (40.4%) followed by moderate (30.5%) and high (28.8%) grades, respectively. Metastases from other parts of the body to the head and neck occurred in 5 patients (8.5%), whereas, in 2 patients (3.4%) the sarcoma metastasized to other parts of the body from the head and neck. Out of the 59 examined patients, 16 cases (27.1%) were observed to have suffered from recurrence.

Discussion

Sarcomas are rare and involve 1% of human cancers, among which currently 4%–10% occur in the head and neck. In the present study, 59 cases (10.06%) of 586 sarcomas patients were observed to suffer from the head and neck sarcomas. In this study, 12 types of sarcoma histopathology were observed, which in turn demonstrates the wide histological variety of these tumors. Pacheco et al. in a study on 36 patients with the head and neck sarcomas, reported 12 types of sarcomas. Lajer et al. observed 15 histopathological types of sarcoma in a study consisting of 36 patients, which are in line with the findings of the present study. Most of the head and neck sarcomas belong to the soft tissue category, and only 20% are bone sarcomas or have a cartilage source. In this study, 59 sarcomas were investigated among which 41 (69.5%) soft tissue sarcomas, and 18 cases (30.5%) were hard tissue sarcomas. In a similar study in the Canadian population, Aljabab et al. observed 80% of sarcomas in the hard tissue and 20% of sarcomas in the soft tissue. In the current study, the most prevalent type of sarcoma, rhabdomyosarcoma, involved 27.1% of the total tumors. Multiple reports have noted that approximately half of rhabdomyosarcomas commonly occur in the head and neck areas. This is in concurrence with the findings of the current study. However, the incidence of head and neck rhabdomyosarcoma can vary. Few studies mention the incidence to be in the range of 8% to 16%, or higher (33.3%) (11). This could be because of geographical and racial differences as well as the different sample size of the different studies. Various studies mention that no geographical preference can be taken into consideration for the occurrence of soft tissue sarcomas. The majority of the patients in our study lived in Yazd, and the rest were from other cities traveled to Yazd for treatment. However, this might affect follow-up of patients in the study centers.

In this study, more than half of the involved patients with the head and neck sarcomas (56%) were females, which is in line with the findings by Bree et al., although in several other studies men have been reported to be affected more than the women. Some of these studies have indicated the predilection of males for the disease is nearly twice as much than females. Due to the rarity of head and neck sarcomas, and limited sample size of most studies conducted in Iran and the world, drawing conclusions and comparisons is not very effective, yet; perhaps one of the reasons for the higher prevalence of females in this study was that women were referred to health centers more than men. As was expected, sarcomas of the head and neck can occur in any age. In fact, studies have demonstrated that soft tissue sarcomas affects 80%–90% of adults and 10%–20% of children. The mean age of the patients involved in this study was 32.22 ± 8.31 years which supports the findings of the studies conducted by Pacheco et al. and Dudhat et al. who noted a similar average mean age of 39.7 ± 25.1. However, Epstein and Gorsky reported the mean age of 40.4 years for this disease. Moreover, Mendenhall et al. reviewed the literature published between 1972 and 2000, and indicated the mean age of 50–55 years for the head and neck sarcomas, though findings of some studies propose that generally sarcomas involving the head and neck affect younger people including children and teenagers compared to squamous cell carcinoma.

In the present study, the anatomical distribution of most of the head and neck sarcomas included the jaw bone as well as the soft tissue of head and neck. Kraus et al. also indicated these two areas as the most prevalent involved locations with the head and neck sarcomas. Tajudeen et al. found the nasal cavity and sinuses as the most commonly involved locations in 22% of his patients. Penel et al. reported a 39.3% involvement in the neck tissue that is consistent with the findings of the current study. In the present study, 5 patients (8.5%) were found to have metastasis from other parts of the body to the head and neck. Breast is the most common site of tumor metastasis to the bone of the jaw, while the lungs involves the most frequent source for metastasis to the soft tissue of the mouth and teeth. In 30% of cases, metastasis in the mouth has been found to demonstrate the first sign of an undiscovered cancer in another part of the body. Compared to other head and neck cancers, among which currently 4%–10% occur in the head and neck.
neck neoplasms (e.g., squamous cell carcinoma), soft tissue sarcomas have a lower rate of regional metastasis.\(\text{(39)}\) In this study, only 2 cases (3.4%) had metastasis to other parts of the body, whereas in a study conducted by Tajudeen et al.\(\text{(9)}\) metastasis to lymph nodes was 6.5% and neural invasion was observed in 6.5% of the cases. Salcedo-Hernández et al.\(\text{(9)}\) reported 50% of soft tissue sarcomas of the head and neck involving metastasis.

Singh et al.\(\text{(31)}\) reported local recurrence in 42% of patients and 42% of metastatic disease development in the lungs. Probably in this study, one reason for the low figures of head and neck sarcoma metastasis to other parts of the body is the lack of follow-up of individual patients specifically from other provinces, who included a large portion of the study sample.

Recurrences of the sarcomas were observed in 27.1% of patients in this study. Because the patients were not actively followed up in order to evaluate recurrence, in reality, the recurrence rate in this study might have been more than what is being reported here. It has been demonstrated that local recurrence in head and neck sarcomas is more than that of other organs\(\text{(28, 40-43)}\), which is probably due to the fact that reaching negative margins of tumor is more complex during sarcoma surgery of the head and neck.\(\text{(44)}\)

Regardless of the location and size of the tumor, one of the main factors for prognosis with sarcomas is the tumor histologic grade.\(\text{(45, 46)}\)

In this study, the majority (40.7%) of sarcomas were low-grade tumors, while 30.5% and 28.8% belonged to average and high grades respectively. However, Tajudeen et al.\(\text{(9)}\) reported 35% of their cases as high-grade sarcomas.

### Conclusion

The head and neck sarcomas are rare tumors that demonstrate a high variability in histology. In the current study, soft tissue sarcomas were generally much more prevalent than hard tissue sarcomas, among which rhabdomyosarcoma was the most common soft tissue sarcoma and osteosarcoma was the most common hard tissue sarcoma. Moreover, the age and gender prevalence, as well as the involved anatomic location in the studied population was similar to those of most other studies. However, our results, for the first time, provide an insight into the prevalence of head and neck sarcomas in Yazd, Iran.

The weak points of this study were the incomplete medical and pathological evidence of the patient and the patients were referred to other treatment centers and IHC (ImmuNoHistochEstry) results were unavailable in some cases.

Abstract

Introduction:
Injection of local anesthesia during dental procedures can induce metabolic changes. The purpose of this study was to evaluate the changes in the serum blood glucose levels after the injection of lidocaine with a vasoconstrictor during tooth extraction.

Materials and methods:
In this clinical trial study, we enrolled 60 patients. We extracted mandibular teeth by using inferior alveolar nerve block. We took a finger blood sample test from each enrolled patient immediately before and 10 min after local anesthesia administration. The anesthetic solution (1.8 mL carpule) contained lidocaine and 1:80,000 epinephrine. It was injected through the inferior alveolar nerve after negative aspiration. Only one carpule was injected into each patient. This study is approved by the ethics committee of the research center of Azad University of Medical Sciences.

Results:
The mean age of the patients in our study was 39.54 ± 15 years. Thirty-five patients were male, and 25 were female. The serum blood glucose level was 111.6 ± 25.47 mg/dL before local anesthesia and 115.3 ± 24.39 mg/dL after tooth extraction (P = 0.418). Eleven female patients and four male patients had a reduction in the blood glucose levels after injection. There was a significant difference between these groups (P = 0.01).

Conclusion:
According to our findings and previous reports, using local anesthesia during tooth extraction does not induce hypoglycemia and could increase the serum blood glucose level in individuals.

Key words:
•Anesthesia •Local •Epinephrine •Glucose •Lidocaine •Tooth Extraction
This study was performed between February and May 2014. We used a convenient, time-based sequential sampling method. Informed consent was given by all patients. We included all adult individuals who were referred to our department for mandibular tooth extractions, and we excluded patients who underwent tooth extractions both in mandible and maxilla or had known histories of diabetes, infection, or any contraindications for using epinephrine.

Our local anesthesia solution (1.8 mL carpule) contained lidocaine and 1:80,000 epinephrine. It was injected in 1 min through the inferior alveolar nerve after negative aspiration. Only one carpule was injected in each patient.

We took a finger blood samples immediately before and 10 min after the administration of local anesthesia. We used a glucometer (Accu Check Active, model GC, Germany) to measure blood glucose in our samples.

Statistical analyses were performed by using Statistical Program for Social Sciences software (SPSS) version 18. Paired t-test and chi-square test were used for data analyses. The significance level (P) was set at 0.05.

Serum Blood Glucose Levels after Local Anesthetic Injection

Introduction

Tooth extraction is one of the most common and frequent dental procedures, which is considered a stressful and painful intervention.\(^1\)\(^,\)\(^2\) If patients’ pain can be soothed, therapeutic procedures will be carried out in a more acceptable situation and patients’ pain threshold will increase.\(^3\)

Lidocaine is the most common local anesthetic material in dentistry. Lidocaine was introduced by Nils Lofgren in 1943 and used for the first time as a local anesthetic material in 1948. One of the most important concerns about local anesthetic injection is its systemic effects.\(^4\)

The most common complications after lidocaine injection are vasovagal shock, hyperventilation syndrome, tachycardia, shivering, and the loss of consciousness. Injection procedures cause pain and induce secretion of endogenous catecholamine, which could have a synergism effect with the vasoconstrictors in the local anesthetic material, leading to some side effects.\(^5\)\(^,\)\(^6\) Using epinephrine along with local anesthesia can also induce metabolic changes.\(^7\)

During anesthetic material injection, some individuals experience some unpleasant situations, such as paleness and losing consciousness, and one of the supportive medications in these cases is using glucose.\(^8\)

Activation of the sympathetic system by stress and epinephrine injection can increase the blood glucose level in patients who undergo dental procedures, such as tooth extraction. Dental surgery with local anesthetic injection can increase catecholamine release, blood glucose, and insulin.\(^9\)

The aim of this study is to evaluate the serum blood glucose level changes after local anesthesia by using local anesthetic in tooth extractions.

Materials and Methods

In this clinical trial study, we evaluated the effect of local anesthetic, by using lidocaine and epinephrine, on the blood glucose concentration in patients who underwent teeth extractions. This study was conducted at the Department of Oral and Maxillofacial Surgery in the dental college, and it was approved by the ethics committee of the research center of Azad University of Medical Sciences. This trial is registered with RCT ID: AEARCTR-0000445.

In this study, we had evaluated 60 individuals. Thirty-five (58.3%) were male, and 25 (41.7%) were female. The mean age in our study was 39.54 ± 15 years. Most patients underwent molar tooth extraction. In two patients (3.3%), we extracted their first tooth; only in one participant tooth number four was extracted, and in nine patients (15%), we extracted tooth number five. Forty-eight patients underwent molar tooth extraction (16 patient for each tooth). Before injection, the mean blood glucose level in patients was 111.6 ± 25.47 mg/dL, and 10 min after lidocaine injection, the mean blood glucose was 115.3 ± 24.39 mg/dL. Paired t-test showed that there was no significant difference in blood glucose levels in patients before and after injection (P = 0.418). Before local anesthesia, in 42 patients, the blood glucose level was higher than 100 mg/dL, and after lidocaine injection, in 51 participants, the blood glucose level was higher than 100 mg/dL. Chi-square test showed that there was a significant change in the number of patients who had...
blood glucose levels higher than 100 mg/dL after lidocaine injection (P = 0.03). Nine patients had blood glucose levels lower than 100 mg/dL, and 41 participants had blood glucose levels higher than 100 mg/dL both before and after tooth extraction. After anesthesia injection, in 45 patients (75%), blood glucose levels were increased, and in 15 patients (25%), it was decreased. Among female participants, in 11 patients, blood glucose levels were decreased; in contrast, among male participants, in only four patients, blood glucose levels were decreased. Chi-square tests showed there was a significant difference between groups (P = 0.01).

We also divide patients in to two groups: molar and non-molar tooth extraction. Forty-eight patients underwent molar and 12 underwent non-molar tooth extraction. The blood glucose level of 13 patients in the molar group and two patients in the non-molar group was decreased. Figure 1 summarizes the distribution of blood glucose levels in patients before and after local anesthesia administration. During our study, vasovagal shock occurred in one patient. The blood glucose level was 94 mg/dL before and 98 mg/dL during his shock, and it was 102 mg/dL when he was stabilized.

![Figure 1](image.png)

**Figure 1.** Distribution of 60 patients before and after local anesthesia based on their blood glucose levels.

**Discussion**

In this clinical trial study, we evaluated glucose levels in 60 patients before and after tooth extraction. There was no significant difference before and after our procedure in patients’ blood glucose levels. Between male and female participants, blood glucose level in female patients was significantly reduced after injection (P = 0.01). Only in one individual was vasovagal shock observed. No hypoglycemic state was detected in this patient. This could be due to catecholamine release and cortisol secretion following anxiety, fear, and pain during injection in this case.

Tily et al. evaluated 30 diabetic and 30 healthy individuals in 2007. They used local dental anesthesia (1.8 mL carpule each) containing 1:80,000 epinephrine and evaluated patients before and 10 min post-extraction. They showed that there was no significant difference in blood glucose concentrations before injection and 10 min after extraction in healthy people compared with diabetic patients. There was no correlation between blood glucose changes and the number of carpules injected, number of teeth extracted, and the gender of the patients; however, there was a significant difference between their diabetic patients who used and who did not use their medications. Our results agree with their findings.

In some other studies, it has been shown that local anesthetic administration can increase norepinephrine in plasma but there is a subtle increase related to the severity and extension of the dental procedure. The blood glucose concentration is related to the epinephrine plasma
concentration and is different from norepinephrine secreted by the sympathetic system.\textsuperscript{11-13} An increased blood glucose level is observed in the presence of epinephrine in local anesthetic materials. Epinephrine has gluconeogenic hormonal activity. After epinephrine infusion, blood glucose concentration increased rapidly during 15 min and returned to the baseline after 2 h.\textsuperscript{14, 15} Bortoluzzi et al. included 37 Brazilian individuals in their study to evaluate hemodynamic and glucose measurement changes in patients who received a local anesthetic and a vasoconstrictor (LAVA; 2% mepivacaine with adrenaline 1100,000). They reported that their evaluated parameters, including systolic blood pressure, diastolic blood pressure, heart rate, and glucose levels, have no significant changes in healthy individuals.\textsuperscript{16} Our results are consistent with their report. In both studies, there was no significant difference before and after dental procedures in glucose levels.

In local anesthetic materials, epinephrine can penetrate to blood circulation and lead to glucose level increase after injection. This change happens after injection and before dental extraction. It is important to know changes in the hemodynamic state and blood glucose after local anesthetic injection to manage some emergent conditions that may occur immediately after injection.

As it was mentioned in the results section, there was a patient with vasovagal shock in our study. According to his different blood glucose levels, there was no hypoglycemic state in this patient. This situation can be explained by catecholamine release and cortisol secretion following anxiety, fear, and pain during injection in this patient.

\textbf{Conclusion}

In many situations during dental procedures, after anesthetic injection, the clinicians encounter emergencies, such as dizziness or loss of consciousness. In these situations, many clinicians begin to administer intravenous fluids with glucose to treat hypoglycemia; however, according to our results and previous studies, blood glucose levels not only decrease after local anesthetic injection but also increase due to injection, pain, and emotional stress.

Abstract

Introduction:
The major demand for orthodontic treatment is associated with esthetic complaints rather than with the severity of occlusal irregularities. This study evaluated the relationship between orthodontic treatment need based on index of complexity, outcome, and need (ICON) and orthodontic-specific quality of life (QOL) among high school students in Shiraz.

Materials and methods:
Based on the correlation between ICON and QOL score (r = 0.254) with α = 0.05 and an estimated power of 80%, 118 high school students (49 girls and 69 boys) aged 15-18 years were selected for this analytical cross-sectional study. The students were randomly selected. The need for orthodontic treatment was determined according to ICON and was compared with QOL, which was assessed using Cunningham’s questionnaire. Data analysis was performed by SPSS-21 using Spearman’s correlation coefficient and Mann-Whitney tests. (p<0.05)

Results:
Analysis based on Spearman’s correlation coefficient, showed no significant association between QOL score and ICON (r=0.95, p=0.282), Mann-Whitney test did not show a significant difference between boys and girls. QOL score was considerably higher in boys (median = 18.50, mean ± SD = 14.82 ± 18.5) compared with girls (median = 9.00, mean ± SD = 14.3 ± 15.02) (p = 0.58).

Conclusion:
No significant difference among boys and girls in relation to orthodontic treatment need was observed, although girls had a significantly lower QOL score than boys. Correlation between orthodontic treatment need and its impact on QOL was also not significant. Therefore, dental esthetics has a greater impact on social acceptance and self-concept among girls.

Key words:
•Index of Orthodontic Treatment Need •Quality of Life •Students
Evaluating the relationship between orthodontic treatment need and oral health-related quality of life

Introduction

Malocclusion, more than being a disease, is considered as a deviation from social esthetic norms. The primary expectation from treatment is improvement in oral function and patient’s appearance. Such a treatment leads to improved psychosocial status, increased self-esteem, and less anxiety and stress while interacting with social groups. The major demand for orthodontic treatment is associated with esthetic complaints rather than with severity of the occlusal irregularities and the subsequent negative effects on dental health.

Quality of life (QOL) is an ambiguous and general term, used in a wide range of contexts. The World Health Organization (WHO), defines QOL as the individual’s perception of their position in life in the context of culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. Oral health-related QOL is a more specific term that concerns the impact of oral and dental health status on an individual’s QOL. Oral and dental health is defined as a set of standards that enables an individual to eat, speak, and socialize without active disease, discomfort, or embarrassment. Oral health has a direct effect on psychological and functional status. Therefore, it profoundly affects enhancement of the overall sense of well-being. In this context, orthodontic treatment could serve as an aid in improving function, and esthetics and, as a result, enhance oral health-related QOL.

In the past 50 years, numerous indices have been developed to evaluate the need for orthodontic treatment. These occlusal indices have been developed based on the type of malocclusion and its negative effects on oral health to assess orthodontic treatment need. Among these indices, the index of complexity, outcome, and need (ICON) is worth mentioning.

One of the QOL assessment tools, associated with orthodontic status, is a questionnaire designed by Cunningham in 2001. Cunningham developed this assessment tool to evaluate orthodontic-specific QOL in orthodontic patients with dento-facial deformities, and also showed its validity and reliability in his studies; He introduced this questionnaire as a useful assessment tool for evaluating oral health-related QOL in clinical studies.

Several studies have shown a significant correlation between QOL and oral and orthodontic status; however few other investigations reported contrasting results. Thus due to such contradictory results, the latest establishment of ICON, the lack of sufficient regional studies on this subject, and the effect of regional, social, and cultural factors on QOL, the present study aimed at evaluating the relationship between orthodontic treatment need based on ICON and orthodontic-specific QOL among high school students in Shiraz.

Materials and Methods

This analytical cross-sectional study was conducted on a sample of 118 high school students (49 girls and 69 boys) aged 15-18 years, which was based on the correlation between ICON and QOL score (r = 0.254) with α = 0.05 and an estimated power of 80%.

The subjects were randomly selected from four high schools (two boys’ and two girls’ high schools). Because the examination of the students was possible only through permission from Shiraz education office, high schools located in four different regions were selected by an educationalist. Each student was numbered in the educational system. By using the table of random numbers, 118 students were randomly selected for the present study. The list of selected students was checked with school authorities to exclude students with depression, bipolar and body dysmorphic disorders.

Other exclusion criteria were: history of orthodontic treatment and currently under treatment. Individuals who needed orthodontic treatment or were currently under treatment because of a diagnosed psychological disorder were also excluded.

Furthermore, before the start of the study, a letter was given to the parents/guardians of the students to seek consent for their cooperation to participate in the study. This letter also served to inform the parents/guardians about the examination procedure and to assure them of the confidentiality of any information collected. Only positive consent was accepted.

Measuring the QOL index:

Cunningham’s questionnaire was used to
assess QOL. The validity of the questionnaire was checked and confirmed by a group of orthodontists, and subsequently the required changes were applied. Cronbach’s $\alpha$ ($\alpha = 0.82$) was adopted for determining the reliability. The questionnaire was also further checked and edited by a sociologist.

Before completing the questionnaire, necessary instructions were given to the students. They were asked to fill the questionnaire according to their personal opinion.

**Determining the need for orthodontic treatment using ICON:**

In order to obtain accuracy in the use of ICON, four orthodontic residents underwent training and calibration exercise. Inter-examiner reliability was assessed under the supervision of a board-certified orthodontist, and intra-examiner reliability was evaluated within 2 weeks. The inter- and intra-examiner reliability values were 89% and 90%, respectively.

For measuring ICON, oral examination was performed using a mouth mirror. Dental esthetics, crowding, and spacing in the upper arch, crossbite, overbite, and molar relationships were evaluated. Each subject was given a grade from 1 to 10 according to the standard form of esthetics. Based on the severity of crowding and spacing in the upper arch, each subject was given a grade from 0 to 5. Subjects were given a score of 1 in the case of posterior cross-bite, and 0 if no posterior cross-bite. Incisor bite was scored 1-3, and occlusion was graded 0-2.\(^{(9)}\)

Data from the questionnaire were classified. QOL was measured according to these data and was compared with the average treatment need diagnosed by the dentist according to the ICON. After data collection and classification, statistical analysis was performed using SPSS 21. Spearman’s correlation coefficient and Mann-Whitney tests were used for data analysis. ($p<0.05$)

**Results**

Analysis based on Spearman’s correlation coefficient, showed no significant association between QOL score and ICON ($r = 0.95$, $p = 0.282$). There was also no significant difference between QOL score and ICON among the two genders in the study (Table 1), based on Mann-Whitney test. However, QOL score was considerably higher in boys (median = 18.50, mean ± SD = 14.82 ± 18.5) compared with girls (median = 9.00, mean ± SD = 14.3 ± 15.02) ($p = 0.58$) (Table 2).

**Discussion**

Among the different age groups, adolescents are more concerned about their physical appearance; consequently, they become sensitive about their dental appearance and esthetics. This could play a significant role in their psychosocial well-being. This study evaluated the relationship between orthodontic treatment need as perceived by a dentist and its impact on oral health-related QOL, among high school students aged 15-18 years.

Among the different indices, the ICON was selected in this study to determine the need for orthodontic treatment. This index places more emphasis on anterior teeth instead of the whole arch. Moreover, it is simple to use on dental casts and thus could be easily applied in clinical settings. This index was also shown to demonstrate better agreement with the perception of orthodontists regarding the need for orthodontic treatment in comparison with IOTN and PAR indices.\(^{(14)}\)

In the current study, the correlation between need for orthodontic treatment and its impact on QOL was not significant, which is consistent with the results of earlier studies.\(^{(12, 13)}\) However, significant association was also reported by some other studies.\(^{(6, 8, 11)}\) The reason for these contradictory results could be attributed to age, ethical, cultural, and social differences; and variation in subjective perception of QOL. These factors could not be fully considered in the questionnaire.
Evaluating the relationship between orthodontic treatment need and oral health-related quality of life

Nevertheless in order to make a comparison, it should be taken into account that earlier studies that reported a significant association had used IOTN, whereas we used ICON to assess the need for orthodontic treatment. We also assessed the gender differences among the study subjects in terms of QOL. The results indicated that QOL is significantly lower among girls. This finding could be attributed to the fact that dental esthetics has a greater impact on social acceptance and self-concept among girls. In general, with the same severity of malocclusion, girls feel more shy in social contexts and their body self-concept is negatively affected, whereas the same malocclusion might be perceived differently by boys. They might be indifferent or even satisfied, whereas girls usually get concerned about minor irregularities.\(^{(15)}\) Regarding orthodontic treatment need among the study subjects, we found no significant gender difference, which is in accordance with the study by Daniela et al.\(^{(15)}\) This finding indicates a similar prevalence of malocclusion among both boys and girls.\(^{(15)}\) The lower QOL among girls compared with boys despite the same orthodontic treatment need could be attributed to the fact that QOL is measured subjectively based on each person’s self-perception, whereas orthodontic treatment need is objectively determined using specific criteria. One of the primary limitations of this study was the lack of complete cooperation on behalf of the school authorities during filling the questionnaires. Therefore, it is recommended that a more comprehensive study be conducted in a broader context.

**Conclusion**

No significant difference among boys and girls in relation to orthodontic treatment need was observed, although girls had a significantly lower QOL score than boys. Correlation between orthodontic treatment need and its impact on QOL was also not significant. Therefore, dental esthetics has a greater impact on social acceptance and self-concept among girls.

³ Dentistry student of Guilan university of medical science

Abstract

Introduction:
Implants are considered to be a useful treatment for the replacement of lost teeth. Although the success rate and durability of implants are high, the prevalence of peri-implantitis is high as well. The purpose of this study was to analyze the knowledge of general practitioners in the city of Rasht in Northern Iran regarding peri-implantitis and its treatment.

Materials and methods:
This descriptive, cross-sectional research was conducted among general practitioners working in the city of Rasht. They were asked to fill out a questionnaire, which included two parts of personal information; and their knowledge about the peri-implantitis disease.

Results:
Of 100 general practitioners who filled out the questionnaires, between 23-88 % answered correctly with a mean of 54.1%. The knowledge of 6% of dentists was poor, 74% average, and 20% good. There was no meaningful connection between age, sex, and job experience of the dentists and their knowledge of peri-implantitis diseases.

Conclusion:
The rate of dentists’ knowledge in the city of Rasht regarding peri-implantitis diseases and their knowledge of treatment were average. Thus, continuous training sessions and workshops regarding peri-implantitis diseases are suggested for their improvement.

Key words:
• peri-implantitis disease • peri-implantitis • peri-implant mucositis • dentist knowledge

Introduction

An inflammatory change of the implant’s surrounding tissue is called peri-implantitis. This lesion is the most common complication in dental implants. Implant failures include primary and secondary failures. Surgical trauma, lack of primary stability, and bacterial infection are primary failures.

Secondary failures result from prosthesis placement, bacterial infection, and mechanical overload. Peri-implantitis is the secondary failure of dental implants. Based on the tissue involvement, the severity of peri-implantitis is divided into two categories: peri-implant mucositis and peri-implantitis. Peri-implant mucositis is a reversible inflammation of the surrounding tissues of functional implants and does not result in any bone loss. Bleeding on probing, pus excretion, and 4-5 mm pocket depth are the clinical signs of this disease.

While, peri-implantitis is a multi-factorial disease that is affected by microbial pathogens and the host’s inflammatory response, biomechanical factors associated with additional forces can affect the implant as well. This increase in microbial activity disrupts the host response balance, precipitating an inflammatory reaction in the tissue surrounding implant leading to bone loss. Therefor, continuation of stimulation causes to periodontal or peri-implant tissue destruction. Increased pocket depth (>5 mm), bleeding, pus excretion on probing, peri-implant tissue bone loss, and circumferential crater are clinical signs of the disease.

Microorganisms have an important role in the development of peri-implantitis. There is a high proportion of pathogens, which are involved in periodontal disease, particularly gram-negative anaerobic bacteria such as P. gingivalis, Tanneraella forsythia, and Troponema denticola. Given that there are not clear microbiological differences between moderate and severe peri-implant mucositis and peri-implantitis, we can suggest that in most cases, peri-implant mucositis gradually turns to peri-implantitis.

Other factors affecting peri-implantitis are patient-related factors such as previous periodontitis history, diabetes mellitus, genetic factors, poor oral hygiene, smoking and alcohol consumption. Implant-related factors include: lack of keratinized tissue around implant, mechanical overload, deeply positioned implant, excessive cement retained, restoration-abutment poor insertion, over contoured restoration, improper implant position and implant surface properties. Recent research on the long-term success of implants has indicated the high incidence of peri-implant mucositis and peri-implantitis. Infections caused by anaerobic bacteria are the primary inflammatory cause of peri-implants.

In the 6th European Periodontal Workshop the incidence rate of peri-implant mucositis (12-40% in implant sites) was 28 to 56%. In the present, more people are keeping their natural teeth for more years, however, people demand improvement in function and beauty and thus in the quality of life, moreover than oral health care. In the past, dental implants were performed in specialized centers, but today the number of treatments performed by general practitioners is rapidly increasing.

Accurate diagnosis of peri-implantitis disease is essential for its proper control: most studies have focused on dentists’ knowledge of dental implants. No studies regarding peri-implantitis diseases were found to have been conducted before done, therefore, in this study, dentists’ knowledge of peri-implantitis and its related treatment was assessed. It was a descriptive, cross-sectional study to provide appropriate educational content.

Materials and Methods

This descriptive, cross-sectional study was done among general practitioners working in the city of Rasht in 2014. The study population included all general practitioners in private practice or employed in clinics in the city of Rasht. The list of names and addresses of all active general practitioners in the city of Rasht (capital to the province of Guilan) were taken from the Dental School of Medical Council. The sampling method for this study was “convenience sample size” and 96 dentists were included. The information in this research was obtained from the assessment of dentists’ knowledge, by the researcher-developed questionnaire. The questionnaire did not ask about their names or addresses and had 2 parts: In part 1, personal information about age, sex, job experience, and history of attendance in implant workshops.
or symposiums was questioned. In part 2, they were asked about etiology (questions 1-4), clinical diagnosis (questions 5-8) and peri-implantitis disease treatment (questions 9-17). For each correct and wrong, a score of 1 and 0 were given respectively. The results varied from 100% (for all correct) to 0% (for no correct answer), and the result was considered to be representative of the dentists’ level of knowledge.

To confirm the questionnaire’s validity, we ask dental school professors of Guilan University of Medical Sciences (GUMS) opinion’s, and, we confirmed the questionnaire’s reliability, by using the Cronbach’s alpha-1 coefficient in a preliminary study.

The project manager herself conducted the general dentist’s offices (or clinics) and provided explanations about the objectives of the study for data collection, after which the questionnaire was given to the dentists. As much as was possible, the questionnaires were filled out in the researcher’s presence; otherwise, after dentists were given a thorough explanation of the study, they were asked to carefully fill out the questionnaire for collect later.

Finally, all 100 questionnaires were collected, and the information went through statistical analysis using SPSS v-19. The relationship between knowledge, age, and job experience was assessed using the Pearson correlation coefficient and the relationship between knowledge, gender, and re-education was analyzed using the Spearman correlation coefficient (statistical significance level P < 0.05). To calculate the correct answer to questions in relation with items, the Chi-Square test with 95% confidence intervals was used, and to determine the factors affecting the account ability logistic regression was used.

**Results**

After the assessment, mean general knowledge of dentists in the city of Rasht was found to be 54.1%. From 100 participants, 69% were male (n=69) and 31% females (n=31). Independent Sample test showed no meaningful differences between the average knowledge of both sexes. (p=0.404).

Regarding background, 53% of the dentists had over 10 years of job experience and 47% had fewer than 10 years of job experience, with 77% having had a history of participation in dental implant workshops or symposiums (23% no history). Using the Independent Sample test there was no significant difference between knowledge and job experience (P=0.179).

Dentists’ distribution based on the field of focus was as follows: 21% prosthetics, 7% surgery, 36% prosthetics and surgery, and 36% none of the above. Using one way ANOVA test, there was a significant statistical relation between the knowledge and field of focus (P = 0.019) with prosthetics in the lead (44.62 %); however, it was not statistically significant.

In Table 2, the number of people who correctly answered less than 33% of the questions, received a poor rating; those answering between 33% and 67% were average; and those with more than 67% were considered good. According to the table in terms of etiology, 25%, 37%, and 38% had poor, average, and good knowledge, respectively. In the field of treatment, 27%, 63%, and 10% had a poor, average, and good knowledge, respectively. In the field of diagnosis, 12%, 37%, and 51% had poor, average, and good knowledge, respectively. Finally, 6% of the dentists had poor, 74% had average, and 20% had good knowledge. The range of correct answers was between 4 and 15: The highest and lowest correct answers were 15 (2% of people) and 4 (3% people) respectively. The mean number of correct answers was 10, with 12 people answering (12% of dentists).

**Discussion**

Despite the high success rate of implants, the increasing rate of peri-implantitis disease has been reported in the literature(11), hence it can be concluded that general practitioners have to increase their knowledge on prevention, diagnosis, and treatment of those diseases. Therefore, continued learning is essential to their professions.

In a 2002 study by Heubener in the United States, the pattern of using implant education in dentistry graduates of Creight University over a period of 10 years (1988 - 1997) was assessed. Results showed that those who passed the implant training in laboratories and workshops had a greater knowledge about implants, did additional implant therapy in their offices and also spent more time on implant education than those who did not...

The questionnaire was divided into 3 part: etiology, clinical diagnosis, and treatment of peri-implant inflammatory diseases. According to the results, in the field of etiology, 38%, 37% and 25% had good, average, and poor knowledge respectively. “Only 10% of dentists had good knowledge of treatment, and, 90% had an average or poor knowledge”. This suggests that the gap in the knowledge of the etiology related to reduced knowledge in the field of treatment. In terms of clinical diagnosis, 51% of the dentists had good knowledge. Greater knowledge of clinical diagnosis than etiology and treatment could indicate the need for higher levels of education.
Assessment of Dentists’ knowledge of Peri-Implant Inflammatory Diseases

in this field.
On the other hand, studies have shown that, in most universities of developed countries, such as United States, Canada, and Western Europe, dental implant clinical training is included in the general dentistry schedule, while in the dental schools of Iran such kinds of studies are not present.(19)
The results of the present study, with a knowledge score of 10.8 for the dentists in the city of Rasht, indicate that implant re-training courses and workshops have not successful in recent years. It seems to be essential to hold re-training courses and conferences, and to distribute training brochures about dental issues to dentists to enhance their theoretical and practical skills of dentists: in particular, about implant and peri-implant diseases.
To provide more statistics and information in dentists’ proficiency and a better and more accurate evaluation of this issue, further studies are needed in other cities of Iran to provide a more comprehensive means for raising dentists’ knowledge levels in the future.

Abstract

Introduction:
Oral squamous cell carcinoma (OSCC), the most common form of oral cancer, requires early diagnosis and suitable treatments. Fascin is a protein involved in cell adhesion and is increased in expression in certain types of carcinomas. The present study was conducted to assess fascin expression in OSCC using an immunohistochemical technique.

Materials and methods:
In the present retrospective study, 25 paraffin blocks of OSCC samples were selected and immunohistochemically stained for detection of fascin expression. Fascin expression rate was calculated as the sum of stained cells (scores from 0 to 4) and staining intensity (scores from 0 to 3).

Results:
Samples collected from 18 men and 7 women, with a mean age of 57.42 years, were assessed, which showed that the most usually affected sites were the gingiva and the tongue. Fascin expression was positive for all the samples and had the highest possible score (24 cases with score 7 and 1 case with score 6). Fascin expression level was not found to have a significant relationship with age, gender, and tumor location (P > 0.05).

Conclusion:
Irrespective of the clinical parameters, fascin expression is possibly involved in the etiology of OSCC; target therapy medicines can therefore be used in the future to treat this malignancy.

Key words:
• Fascin • Mouth Neoplasms • Carcinoma, • Squamous Cell • Immunohistochemistry

Introduction
Oral squamous cell carcinoma (OSCC) is the most common form of oral cancer, accounting for approximately 91% of all oral malignancies.\(^{(1)}\) The etiology of this carcinoma is multifactorial and both internal and external factors might affect its development. Despite using a combination of treatments including surgery, radiotherapy, and chemotherapy, the 5-year survival prospect is perceived in only approximately 40% of the patients and some die due to the secondary complications of cancer.\(^{(2)}\) Although surgery is still an appropriate treatment, it presents certain complications, such as chronic pain, dysphagia, dysphasia, and malformation.\(^{(3)}\) Radiotherapy and chemotherapy also have antitumor effects, but they damage the normal tissue. A better understanding of the molecular mechanisms and identification of the potential of onco-genes in OSCC could lead to the introduction of new adjunctive methods of treatment (molecular targeted therapy) for patients with oral cancer, which would result in fewer complications compared with other methods of treatment.\(^{(4)}\) Local tumor invasion and metastasis account for 90% of treatment failures. This aggressive behavior arises due to multiple phases that lead to the loss of cell adhesion. Fascin is a 55-kDa protein from the family of actin-bundling proteins that contributes a great share to the properties of cell junctions and their increased motility. In recent years, several studies have been conducted on this marker in normal and pathological tissues and several different roles have been attributed to it in the incidence of diseases such as neoplasms.\(^{(5,6)}\)

Given the role of fascin in cell adhesion, this protein may be used as a target for the treatment of OSCC and also as a marker for identifying aggressive malignant cell behaviors. As only a few studies have examined the role of fascin in OSCC \(^{(7-12)}\), the present study was therefore conducted to evaluate the expression levels of fascin in OSCC to gain more knowledge about fascin and OSCC and to also pave way for predicting tumor behavior and for finding a suitable treatment. Furthermore, given that, in many cases, non-smoking young individuals are diagnosed with tongue carcinoma, the present study assessed the relationship between this marker and age, gender, and tumor location.

Materials and Methods
The present study was retrospective and cross-sectional in design. Archived samples at the pathol-ogy laboratory of Taleghani Hospital and a private laboratory were examined and samples with an OSCC diagnosis were selected. Clinical and demographic data such as age, gender, and tumor location were extracted from the patients’ records. Cases with sufficient data on the surveyed variables as well as the corresponding paraffin blocks with complete fixation and adequate tissue and with microscopic features of squamous cell carcinoma were finally selected.

Immunohistochemical (IHC) staining of paraffin blocks
The streptavidin-biotin method was used for staining. All samples were first fixed in 10% buffered formalin and then embedded in paraffin. Sections were prepared with a diameter of 4 mm and then deparaffinized and dehumidified by xylene and alcohol and washed with phosphate-buffered saline (PBS) and then placed in DAKO cytomation (PH = 9) in a microwave for 20 min for fixing the antigens. Internal oxidation was inhibited by addition of 3% hydrogen peroxidase. The slides were then incubated with monoclonal antibody (Dako, Denmark, clone55k-2, Code M3567) for 30 min according to the manufacturer’s recommendations for examining fascin expression. After washing the slides with PBS for 5 min, they were immersed in Zymed streptavidin and incubated for 10 min. In the next step, the slides were exposed to 3,3′-Diaminobenzidine (DAB) hydrochloride as a chromogenic reagent, which produced a brown reaction product. The samples were then counterstained by hematoxylin and a coverslip was placed on them after dewatering.

A sample of Hodgkin’s lymphoma was used as the positive control and the negative control was examined after the elimination of the primary antibody. Vascular endothelium was also taken as an internal positive control.

Method of interpreting the slides
Staining was assumed positive when the cytoplasm of the tumor cells was visibly stained. Fascin expression was determined based on the following items:
1. Percentage score (PS): According to the study conducted by Lee et al. (10), the number of stained cells was determined based on the DAB staining under an optical microscope, which were then divided into four groups. Score 1: less than 10% stained; score 2: 11-50% stained; score 3: 51-80% stained, and score 4: more than 81% stained.

2. Intensity score (IS): Score 0: no staining; score 1 (poor): staining is visible but with some difficulty; score 2 (medium): pale brown (oak); and score 3 (extreme): dark brown. To calculate the final score, PS was added to IS (0-7).

Results

The present study was conducted on OSCC samples of 25 patients with a mean age of 57.42 years (range: 27–90 years), of which 18 patients (72%) were males with a mean age of 59.41 years and 7 (28%) were females with a mean age of 52.57 years. The OSCC samples were mostly collected from the gingiva (10 cases or 40%) and the tongue (8 cases or 32%). In addition, four samples (16%) were collected from the buccal mucosa, two (8%) from the palate, and one (4%) from the lip. Fascin expression was analyzed in the OSCC samples using IHC staining. Fascin staining was cytoplasmic and fascin expression was confirmed in all the samples examined with a high score. All the samples obtained score 3 for their percentage score. For the intensity score, 24 samples obtained score 3 and 1 sample obtained score 2 (Figures 1 and 2).

The assumption in this study was that independent variables, particularly tumor location, were capable of affecting fascin expression. Given that all the samples had high scores in terms of their fascin expression levels (score 7 and, in one case, score 6), it was observed that fascin expression was not related to the patients’ age and gender and tumor location. As the biopsy samples were mostly incisional, with few excisional cases, grading them was not possible. However, the tissues surveyed were primarily differentiated and the majority contained keratin pearls, and no poorly differentiated states were observed under the microscope. Malignant squamous cell islands were fascin-positive with or without the presence of keratin pearls.
Discussion

The present study showed overexpression of fascin in OSCC. Fascin expression level was not found to have a significant relationship with the patients’ age and gender and tumor location. These results are consistent with the results of many other studies conducted on fascin expression and its relationship with gender, age, and tumor location.\(^{7,9,10,11,12}\)

Similarly, Chen et al.\(^{9}\) did not find fascin expression intensity to have a relationship with age, gender, and tumor location and fascin expression percentage to have a relationship with the patients’ age and gender. Although the majority of buccal mucosa samples expressed less than 55% fascin, the tongue samples of OSCC mostly expressed more than 55% fascin, which was statistically significant. Lee et al.\(^{10}\) also did not find fascin expression intensity to have a relationship with the patients’ age and gender. Similar to the present study, they also reported that this protein was expressed in 91.3% of the samples. In the present study, the majority of samples were well differentiated under the microscope and contained keratin pearls (although their microscopic grade could not be determined). All the islands, with or without keratin pearls, overexpressed fascin. Consistent with our findings, Shimamura et al.\(^{11}\) noticed fascin expression in epithelial dysplasia, carcinoma in situ, and also in OSCC, unlike in benign tumors such as papilloma. Therefore, it is quite natural for all of our samples to also overexpress this marker. It was suggested that fascin could be a useful tool for the accurate diagnosis of dysplasia and carcinoma in situ.\(^{11}\) Fascin might therefore be involved in the early stages of carcinogenesis.

In contrast to the results obtained in our study on fascin expression, Alam et al.\(^{7}\) did not detect this protein in 25.19% of the cases and found that it had a poor expression in 41.98% of the samples and was overexpressed only in 32.28% of the cases.\(^{13}\) They also did not find fascin expression in the well-differentiated keratin-pearl-containing cases of OSCC. Moreover, unlike Chen and Alam\(^{7,9}\), other researchers\(^{10,12}\) did not find a relationship between grade, microscopic stage, and fascin expression; however, they found that a relationship was established when lymph nodes were involved. The possible reasons for the disparity of results might be technical errors and the different steps of performing IHC staining, visual counting, using the computer, and the sample size examined. As in previous studies\(^{9,11}\), in the OSCC samples examined in the present study, fascin was primarily cytoplasmic-stained; however, due to its overexpression, the cell membrane was also stained in some cases. Nevertheless, Alam et al. also showed fascin expression in cell membranes in addition to that in the cytoplasm.\(^{7}\) Previous studies showed that fascin is either not expressed in normal oral epithelium or is expressed very poorly.\(^{11}\) An interesting point, however, was that in the study conducted by Papaspyrou et al., 7 cases out of the 19 surveyed cases of normal epithelium showed score 2.\(^{12}\)

The justification for this finding might be that the epithelia might have been derived from the vicinity of the tumor and might have therefore had the same environmental and pathological conditions, thus overexpressing the marker. The epithelia might be normal in macroscopic terms and under an optical microscope and might have experienced structural changes at the molecular level, and our slides also showed epithelia in some cases. However, the epithelium was not the subject for examination as it was in the vicinity of the tumor and hence will not be considered environmentally natural. Alam et al.\(^{7}\) found no relationship between fascin expression and invasion around the nerves. They also stated that fascin overexpression was observed in 17% of the N0 cases, and these patients should therefore be followed up to determine in the future whether fascin can act as a prognostic factor of occult metastasis or not. Papaspyrou et al.\(^{12}\) also concluded that fascin can be used to predict regional lymph node metastasis, and, in contrast to several studies\(^{7,8,10}\), fascin expression was not associated with the reduced survival in their study. To better explain the role of this protein, several studies have investigated its function, including a study conducted by Chen\(^{8}\), who examined the function of fascin from the WNT signaling pathway through the stabilization of β-catenin mutation or the inactivation of APC gene and suggested that it increases the expression of this protein in cancer cells. In addition, Lee et al.\(^{10}\) stated that fascin expression is associated with the loss or reduction of E-cadherin, which is a
significant component of tumor cell invasion, and leads to the loss of cell–cell contact. Alam et al. (7) stated that fascin can disrupt the cell–cell contact and is involved in the formation and progression of primary OSCC tumor. Furthermore, fascin increases MMPs (2,9), which are proteolytic enzymes that digest the basement membrane content and facilitate metastasis. They also found a strong relationship between fascin expression and lymph node involvement, confirming that the marker might facilitate the movement of tumor cells from the primary location to the lymph nodes. In the present study, the IHC staining method was used to examine fascin expression. Other methods can also be used to confirm the IHC staining results; for instance, the RT-PCR for analyzing fascin expression and the Western Blot for assessing fascin levels. (10) However, further tests could not be conducted in the present study due to their high costs and the use of fixed samples. Alam et al. (7) found actin components such as microspikes to be thicker and longer and showed the formation of more filopodia and lamellipodia, demonstrating a visibly increased cell motility in OSCC cell culture. Similarly, in another study on two OSCC cell lines, Chen et al. (8) also concluded that fascin expression might have an essential role in the regulation and development of OSCC.

Conclusion
Given the limitations of the present study, the results showed that fascin is overexpressed in OSCC samples, but its level is not associated with gender, age, and tumor location. Regardless of the clinical parameters, fascin expression is possibly involved in the etiology of OSCC, and target therapy medicines can therefore be used in the future for treating this malignancy.
